An important question to answer in any genetic experiment is how can we decide if our data fits any of the Mendelian ratios we have discussed. A statistical test that can test out ratios is the Chi-Square or Goodness of Fit test. Chi-Square Formula Degrees of freedom (df) = n-1 where n is the number of classes Let's test the following data to determine if it fits a 9:3:3:1 ratio. Observed Values Expected Values 315 Round, Yellow Seed (9/16)(556) = 312.75 Round, Yellow Seed 108 Round, Green Seed (3/16)(556) = 104.25 Round, Green Seed 101 Wrinkled, Yellow Seed (3/16)(556) = 104.25 Wrinkled, Yellow 32 Wrinkled, Green (1/16)(556) = 34.75 Wrinkled, Green 556 Total Seeds 556.00 Total Seeds Number of classes (n) = 4 df = n-1 + 4-1 = 3 Chi-square value = 0.47 Enter the Chi-Square table at df = 3 and we see the probability of our chi-square value is greater than 0.90. By statistical convention, we use the 0.05 probability level as our critical value. If the calculated chi-square value is less than the 0.05 value, we accept the hypothesis. If the value is greater than the value, we reject the hypothesis. Therefore, because the calculated chi-square value is greater than the we accept the hypothesis that the data fits a 9:3:3:1 ratio. A Chi-Square Table Probability Degrees of Freedom 0.9 0.5 0.1 0.05 0.01 1 0.02 0.46 2.71 3.84 6.64 2 0.21 1.39 4.61 5.99 9.21 3 0.58 2.37 6.25 7.82 11.35 4 1.06 3.36 7.78 9.49 13.28 5 1.61 4.35 9.24 11.07 15.09 Copyright © 2000, Phillip McClean The χ^2 statistic is used in genetics to illustrate if there are deviations from the expected outcomes of the alleles in a population. The general assumption of any statistical test is that there are no significant deviations between the measured results and the predicted ones. This lack of deviation is called the null hypothesis (H0). χ^2 statistic uses a distribution table to compare results against at varying levels of probabilities or critical values. If the χ^2 value is greater than the value at a specific probability, then the null hypothesis has been rejected and a significant deviation from predicted values was observed. Using Mendel's laws, we can count phenotypes after a cross to compare against those predicted by probabilities (or a Punnett Square). In order to use the table, one must determine the stringency of the test. The lower the p-value, the more stringent the statistics. Degrees of Freedom (DF) are also calculated to determine which value on the table to use. Degrees of Freedom is the number of classes or categories there are in the observations minus 1. DF=n-1 In the example of corn kernel color and texture, there are 4 classes: Purple & Smooth, Purple & Wrinkled, Yellow & Smooth, Yellow & Wrinkled. Therefore, DF = 4 - 1 = 3 and choosing p < 0.05 to be the threshold for significance (rejection of the null hypothesis), the χ^2 must be greater than 7.82 in order to be significantly deviating from what is expected. With this dihybrid cross example, we expect a ratio of 9:3:3:1 in phenotypes where 1/16th of the population are recessive for both texture and color while $\frac{9}{16}$ of the population display both color and texture as the dominant. $\frac{3}{16}$ will be dominant for one phenotype while recessive for the other and the remaining $\frac{3}{16}$ will be the opposite combination. With this in mind, we can predict or have expected outcomes using these ratios. Taking a total count of 200 events in a population, $\frac{9}{16}(200)=112.5$ and so forth. Formally, the χ^2 value is generated by summing all combinations of: $\frac{(\text{Observed}-\text{Expected})^2}{\text{Expected}}$
